2. Academy for Precision Measurement Science and Technology, CAS, China

INTRODUCTION

We seek to establish a robust method of determining and correcting the misorientation seismic stations with radial and tangential components of teleseismic receiver function (RFs)

METHODS/DATA

Using the amplitude method (PRFamp) and energy (PRFenergy) of P-wave receiver function (PRFs) using varying Gaussian factors with equivalent cutoff frequencies. We estimate the misorientation of 26 permanent seismic stations across West Africa and its adjacent Islands

START

RESULTS

Tests to examine the effect of varying Gaussian factors on the estimates of misorientation are more noticeable in results from stations for which RFs are indicative of 3D or complex structures and islandic stations. Results from both methods show good correlation.

CONCLUSION

PRFamp method proves to be more stable due to their proximity to the statistical mean and standard deviation results. Gaussian factor of 1.5 is recommended as a trade-off. We suggest that multiple approaches be adopted to provide robust bases for the misorientation estimation

INTRODUCTION

- **Accurate seismic station orientation is essential for seismic waveform data quality and seismological studies**
- **In modern seismological observation networks, seismic events are recorded by orthogonally aligned triaxial sensors. Although the assumption holds that single vertical-component sensors do not have misorientation concerns, the two horizontal components involving the BHN (north–south) and BHE (east–west) may have misorientation issues (Niu and Li, 2011; Wang et al., 2016; Doran and Laske, 2017; Ekström and Nettles, 2018; Langston, 2018; Ojo et al. 2019; Zheng et al. 2020)**
- **Previously, misorientation errors have been estimated using tangential components from P-wave energy minimization, P-wave particle motion, and Rayleigh-wave angle of arrival measurements (Doran and Laske, 2017; Ekström and Nettles, 2018; Langston, 2018; Ojo et al. 2019; Zheng et al. 2020)**
- **In this study, we conduct a series of tests involving different α values to investigate the amplitude-based (hereafter referred to as PRFamp) method using the single-point maximum amplitude of RF and energy-based (hereafter referred to as PRFenergy) method that utilize a time window around the maximum amplitude of the P-wave receiver function (PRFs).**
- **We used 26 permanent stations cutting across the Inland, Coastal, and Islandic terrains of West Africa to test our methods.**

P4.2-083

- (a) Coordinate geometry of seismic station relative to the direction of P-wave motion from the source.
- (b) Station components and direction of horizontal components of the P-wave window. R and T are radial and tangential components relative to the seismometer's orientation. R' and T' are radial and tangential components after orientation correction with the angle "Theta" (θ).
- (c) The amplitude and time window in the vicinity of 0 seconds of P-phase of the RRC. The minimum and maximum values for both time and amplitudes vary for different Gaussian factors (α values are (0.5, 1.0, 1.5, 2.5, 3.0, and 5.0))

RESULTS – Search for the best orientation

Oсотuyi et al., 2023 SRL

- The red and blue lines in the plots correspond to objective functions from RRC and RTC
- Consideration of the objective functions involving maximum amplitude of RRC, minimum of RTC, and the energy of the RRC
- The IU-MACI station is an island station for which RFs reveal complex subsurface heterogeneities underlying the station

RESULTS – Misorientation variation with Time and Backazimuth

➤ **Sensor orientation variation with time (black) and sensor orientation variation with back azimuth through the validation periods at the representative**

➤ **Back-azimuthal distribution with sensor misorientation variation through the validation periods at the representative**

Please do not use this space, a QR code will be automatically overlaid

RESULTS – Statistical Analysis

- i(a-f) Frequency and ii(a-f) probability distribution of sensor misorientation estimates from events at representative stations G-TAM, IU-MACI, and MN-RTC
- Misorientation angles > 30° in i(a-f) against (a) Backazimuth and (b) Magnitude in station MN-RTC showing non-Gaussian distribution on the graph

CONCLUSION

- **Misorientation correction shows significant effect on RFs waveforms and RFHV analysis**
- **The effect of heterogeneity was insignificant on PRFamp in comparison with PRFenergy method i.e. the latter is more sensitive to subsurface heterogeneities and/or dipping interfaces**
- **station misorientation errors or accuracy may not be influenced by or dependent on the back-azimuthal distribution of events**
- **In all the stations but one, the stations showed a relatively stable range of misorientation values during the recording period**
- **the number of events used for misorientation estimation could significantly impact the results. A minimum of 30 events are recommend for station orientation analysis**
- **Results from an α of 1.5 are recommended as a trade-off between oversimplification and complications due to subsurface structures**
- **Physical interaction with sensors should be limited. Transmission (telemetry) of waveforms is recommended**
